## Abstract

We present a resonant x-ray scattering study of the octahedral tilt order between 50 K and  $310 \,\mathrm{K}$  in  $\mathrm{La_{7/8}Sr_{1/8}MnO_3}$ . At the La L<sub>II</sub>-edge the resonant (300) reflection probes cooperative tilts of the MnO<sub>6</sub>-octahedra in this material, as verified by a model caclulation as well as a LDA+U study. The investigation of the octahedral tilts as a function of temperature and the comparison to the lattice parameters, the magnetization and the superlattice reflections related to charge and/or orbital order reveal an intimate coupling between electronic and tilt degrees of freedom in  $\mathrm{La_{7/8}Sr_{1/8}MnO_3}$ .

#### A. Introduction

The investigation of the electronic correlations in doped transition metal oxides is an active field of condensed matter research. In particular, the interplay between structural distortions and charge ordering phenomena has attracted a lot of attention. A prominent example for the coupling between structure and charges is the influence of the octahedral tilts on the stripe order in doped cuprates; i.e. the pinning of charge stripes by a potential due to tilts of the CuO<sub>6</sub>-octahedra [1, 2]. The static stripe order which develops in doped nickelates [3] might also be stabilized by a similar mechanism, namely by the cooperative tilting of the NiO<sub>6</sub>-octahedra. Recently, it has been recognized that octahedral tilt order also plays an important role for the physics of doped manganites. In particular, there are indications that the tilting of the MnO<sub>6</sub>-octahedra in LaMnO<sub>3</sub> couples to the orbital degree of freedom [4, 5].

In this article we present a resonant x-ray scattering study of the octahedral tilt order in  $La_{7/8}Sr_{1/8}MnO_3$  which shows several phase transitions as a function of temperature [6, 7]: Upon cooling an orbital ordered state similar to that of LaMnO<sub>3</sub> develops at  $T_{JT} \simeq 280 \,\mathrm{K}$ , where an antiferrodistortive ordering of Jahn-Teller distorted MnO<sub>6</sub>-octahedra occurs [8, 9]. Decreasing the temperature down to  $T_C \simeq 180 \,\mathrm{K}$  leads to the onset of ferromagnetic order, yielding a change of the electrical resistivity from insulating to metal-like in agreement with the double exchange picture. Further cooling leads to a metal-insulator transition at  $T_{CO} \simeq 155 \,\mathrm{K}$ , where a charge and orbital ordered ferromagnetic insulating (FMI) phase is established at low temperatures [10, 11, 12, 13, 14]. This FMI phase contradicts a bare double exchange model, and there is strong evidence that pronounced correlations between magnetism, charges, structure and orbital degrees of freedom stabilize an orbital polaron lattice below  $T_{CO}$  [15].

These results together with the aforementioned connection between the orbital order and the octahedral tilts found in LaMnO<sub>3</sub>, raise the question whether octahedral tilts are important for the stabilization of the various phases in La<sub>7/8</sub>Sr<sub>1/8</sub>MnO<sub>3</sub> as well. In order to elucidate the role of the tilt ordering in La<sub>7/8</sub>Sr<sub>1/8</sub>MnO<sub>3</sub> we have performed Resonant X-ray Scattering (RXS) at the La L<sub>II</sub>-edge which has been shown to be highly sensitive to changes in the octahedral tilt order [4, 16].

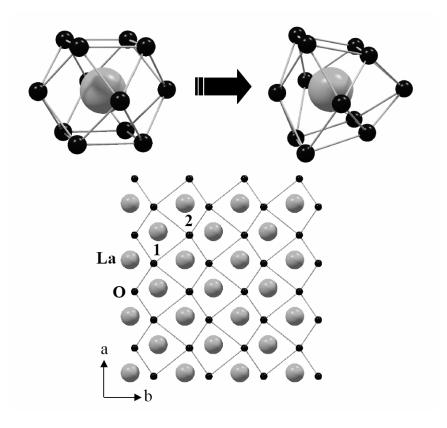

FIG. 1: *Top*: Deformation of the oxygen cage around a lanthanum ion in the orbital ordered phase of LaMnO<sub>3</sub> (the edges of the cage do not represent chemical bonds). *Bottom*: The tilt order in the orbital ordered phase creates lanthanum sites with differently distorted local environments in the orthorhombic *ab*-plane (sublattices 1 and 2).

#### B. Experimental technique

By tuning the x-ray energy to the La  $L_{II}$ -edge the resonant scattering becomes sensitive to changes of the octahedral tilt order. This sensitivity stems from the fact that at the La  $L_{II}$ -edge the resonant scattering process involves  $2p \rightarrow 5d$  transitions in the La sub-bands; i.e. the creation of virtual photoelectrons in an intermediate 5d-state. As the charge distribution of the 5d-states is extended, the influence of the crystal field is large. Therefore, the resonant scattering strongly depends on the local environment of the resonant scatterer. As demonstrated in Fig. 1, the GdFeO<sub>3</sub> type tilt order in the cooperative Jahn-Teller distorted phase of LaMnO<sub>3</sub> leads to a strong deformation of the oxygen cage around the La-site. Moreover, the tilt order of the MnO<sub>6</sub>-octahedra creates sublattices of La-sites with differently distorted local environments (1 and 2 in Fig. 1). This makes it possible to observe

symmetry forbidden reflections at the La  $L_{\rm II}$ -edge, which reflect changes of the octahedral tilt order, as described in more detail in the following Sec. C.

The RXS experiment has been performed using a vertical scattering geometry at the wiggler beamline W1 at HASYLAB. This beamline is equipped with a Si(111) double monochromator which provides an energy resolution of about 2 eV at the La L<sub>II</sub>-edge. The sample was mounted on the cold finger of a closed cycle cryostat which was itself mounted on a standard Eulerian cradle. The incident slits have been chosen in order to give a polarization  $P = I^{\sigma}/(I^{\sigma} + I^{\pi}) = 0.93$  of the incident beam, where  $\sigma$  and  $\pi$  refer to polarization directions perpendicular and parallel to the scattering plane, respectively. For the polarization analysis at the La L<sub>II</sub>-edge the (004) reflection of graphite with a scattering angle of  $2\Theta \simeq 77.61^{\circ}$  has been used, leading to a cross talk between  $\sigma\sigma$  and  $\sigma\pi$  channels of 6% as determined from the (400) Bragg reflection. The La<sub>7/8</sub>Sr<sub>1/8</sub>MnO<sub>3</sub> single crystals have been grown using the traveling floating zone method [17] and for the RXS experiment a sample with a polished (100)-surface has been prepared (surface roughness  $\simeq 5 \, \mu$ m).

#### C. Model calculation

The observation of symmetry forbidden reflections in LaMnO<sub>3</sub> for photon energies around the La L<sub>II</sub>-edge, can be understood in terms of a model calculation based on a purely ionic picture: When the x-ray energy is tuned to the La L<sub>II</sub>-edge the scattering process involves  $2p \rightarrow 5d$  transitions. Adopting the dipol-dipol approximation the relevant term of the atomic form factor f near the La L<sub>II</sub>-edge can be described by a second rank tensor  $\hat{f}$  with respect to the beam polarization, which is given by [18, 19]:

$$\hat{f}^{(\alpha,\beta)} = \frac{1}{m} \sum_{j} \frac{\langle 2p|p_{\alpha}|5d_{j}\rangle\langle 5d_{j}|p_{\beta}|2p\rangle}{E(5d_{j}) - E(2p) - \hbar\omega - i\Gamma/2}$$

Here,  $|2p\rangle$  and  $|5d_j\rangle$  denote the initial 2p state and the 5d intermediate states, respectively. E(2p) and  $E(5d_j)$  are the corresponding energies, m is the (reduced) electron mass,  $p_{\alpha,\beta}$  ( $\alpha, \beta = 1, 2, 3$ ) represents the components of the momentum operator and  $\Gamma \sim 1 \,\text{eV}$  is the life time broadening width of the 2p core hole. Since the asymmetric unit of the LaMnO<sub>3</sub> structure contains only a single lanthanum site, the structure factor tensor used for the kine-

matic calculation of the diffracted intensities reads (temperature effects are neglected) [20]

$$\hat{F}(\mathbf{Q}) = \sum_{q} \hat{f}_{g} e^{i\mathbf{Q} \cdot \mathbf{r}_{g}} \quad .$$

In the above equation the sum runs over the symmetry operations g of the space group,  $\hat{f}_g = R_g \, \hat{f} \, R_g^t$  is the scattering factor tensor transformed by the rotational part  $R_g$  of g,  $\mathbf{r}_g$  is the position vector of the corresponding symmetry related lattice site and  $\mathbf{Q}$  stands for the scattering vector. Note, that due to the above transformation of  $\hat{f}$  the form factor tensor of the lattice sites 1 and 2 in Fig. 1 is different. For a *Pbnm*-symmetry, which we refer to throughout this paper, the intensities of the 'forbidden' (300) reflection in the  $\sigma\pi$ - and the  $\sigma\sigma$ -channel are [21]

$$I_{\sigma\pi} \propto (f_{12}\cos\theta\cos\Phi)^2$$
 and  $I_{\sigma\sigma} = 0$ ,

where  $\vartheta$  is the Bragg angle and  $\Phi$  is the azimuthal angle, which describes the rotation of the sample around the scattering vector [9]. In the ionic picture the matrix element  $f_{12}$  can then be calculated using the Wigner-Eckhart theorem, in order to get an idea of its dependence on octahedral tilts and distortions. For a  $2p_{1/2}$  initial state and the 5d intermediate states of  $t_{2g}$  and  $e_g$  symmetry it follows: (the same result holds for a  $2p_{3/2}$  initial state)

$$f_{12} = \frac{|M|^2}{E(5d_{yz}) - E(2p) - \hbar\omega - i\Gamma/2}$$
$$- \frac{|M|^2}{E(5d_{xz}) - E(2p) - \hbar\omega - i\Gamma/2}$$
$$\propto |M|^2 \Delta \times \mathcal{L}_{\Delta}(\hbar\omega)$$

( $|M|^2$ =const. has the unit of an energy,  $\Delta = E(5d_{xz}) - E(5d_{yz})$ , and  $\mathcal{L}_{\Delta}(\hbar\omega)$  is a Lorentzian centered at  $\Delta$ ). Since the  $t_{2g}$ -symmetric  $5d_{xz}$ - and  $5d_{yz}$ -orbitals are degenerate in a cubic crystal field, the intensity of the (300) vanishes in this case ( $\Delta = 0$ ). But octahedral tilts and distortions lower the symmetry of the local environment, thereby lifting orbital degeneracy ( $\Delta \neq 0$ ). In this case  $I_{\sigma\pi}$  does not vanish and the (300) reflection is observed at the La  $L_{II}$ -edge. As a result, the ionic model yields the occurrence of the resonant (300) reflection at the La  $L_{II}$ -edge for non-vanishing octahedral tilts and/or distortions with three important main characteristics, namely (i) pure  $\sigma\pi$ -scattering, (ii) a  $\sin^2$ -azimuthal dependence and (iii) a resonant increase of the intensity at the La-edges.

However, the ionic picture has also its limitations. More specifically, the dependence of  $f_{12}$  on the values of the tilt angles and the size of the distortions can not be calculated accurately. This is because band structure effects, which are relevant for the spatially extended La:5d intermediate states, are not taken into account in this description. Therefore, the ionic localized valence charge model should only be used as a guide, whereas a rigorous discussion should always refer to the full band-structure calculation.

In a previous publication, the effect of structural distortions on the (300) reflection at the La-edges has been calculated by means of LDA+U, which provides an appropriate description for the effects of the band structure mentioned above [16]. Besides the octahedral tilts also distortions of the octahedra have been investigated. But the LDA+U calculations show that the intensity of the (300) reflection at the La  $L_{\rm II}$ -edge is mainly given by octahedral tilts, whereas the contribution due to distortions of the octahedra has been found to be negligible.

To conclude, the above results show that the resonant scattering at the (300) position in the  $\sigma\pi$ -channel at the La L<sub>II</sub>-edge probes the tilt structure of La<sub>7/8</sub>Sr<sub>1/8</sub>MnO<sub>3</sub>.

#### D. Results

#### 1. Energy and azimuthal dependence

Figure 2 displays the energy dependence of the (300) reflection around the La L<sub>II</sub>-edge at 50 K in the FMI phase. The energy dependence displays a sharp (FWHM $\simeq 5\,\mathrm{eV}$ ) but asymmetric peak at 5897 eV and a broad increase of the resonant intensity around 5926 eV. Above 5940 eV and below 5890 eV the intensity at the (300) position vanishes. The observed features of the energy dependence shown in Fig. 2 resemble the calculated energy dependence at the La L<sub>II</sub>-edge obtained by the LDA+U calculations mentioned above. In the inset of Fig. 2 the pronounced azimuthal dependence of a rocking scan through the (300) reflection at 5897 eV can clearly be observed. Referring to the inset, the case  $\Phi = 0^\circ$  corresponds to a polarization of the incident beam parallel to the a, b-direction, whereas this polarization is perpendicular to the ab-plane for  $\Phi = 90^\circ$ . Obviously, the intensity is continuously reduced to zero by increasing  $\Phi$  from 0° to 90°, excluding multiple scattering as the origin for the intensity at the (300)-position. The polarization analysis performed using the (002) reflection

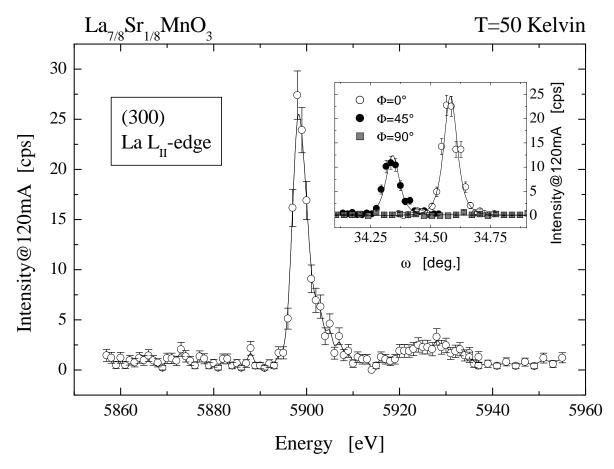

FIG. 2: Energy dependence of the (300) reflection around the La  $L_{II}$ -edge in the FMI-phase at 50K. The azimuthal dependence of a rocking scan at the same temperature and at 5987 eV is shown in the inset. These measurements have been performed without analyzer.

of graphite reveals that, within the experimental errors, the resonant scattering at the La  $L_{II}$ -edge occurs only in the  $\sigma\pi$ -channel. These observations are in nice agreement with the results of the model calculation presented in Sec. C and the predictions of the LSDA+U study [16], verifying that the observed resonant (300) reflection in the  $\sigma\pi$ -channel probes the octahedral tilts in  $La_{7/8}Sr_{1/8}MnO_3$ .

In Fig. 3, the energy dependences of the (300)-reflection taken at 50 K, 157 K, 200 K and 285 K are compared. On the one hand, it can be seen that the shape of the resonance curve is not affected by increasing the temperature; i.e the overall line shape of the energy dependence is the same in the FMI-phase (T <  $T_{CO} \simeq 155 \,\mathrm{K}$ ), the cooperative Jahn-Teller distorted phase ( $T_{CO} < T < T_{JT} \simeq 280 \,\mathrm{K}$ ) and above  $T_{JT}$ . The data also verify that the resonant scattering is always dominant, while possible non-resonant contributions related to temperature dependent lattice symmetry changes (see below) can be completely neglected

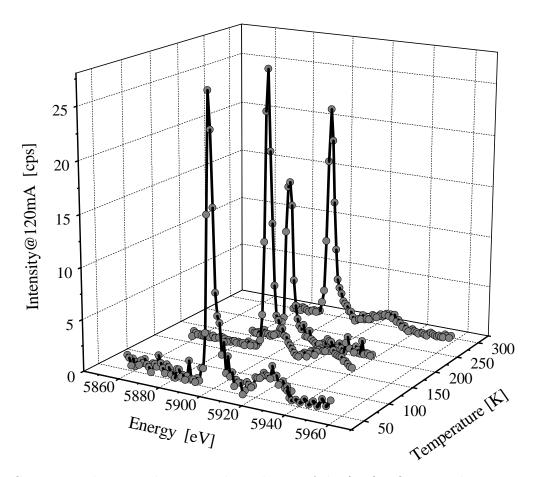

FIG. 3: Comparison between the energy dependences of the (300) reflection taken at 50 K, 157 K, 200 K and 285 K. The shape of the resonance curve is unchanged with increasing temperature whereas the intensity is temperature dependent.

[22]. On the other hand, it becomes apparent that the intensity of the (300) reflection is strongly temperature dependent as will be discussed in the following.

#### 2. Temperature dependence

Figure 4 (a) deals with a comparison between the temperature dependences of the a, baxis, the integrated intensity of the (4,0,0.5) and the (300) reflection measured at the Mn
K-edge, as well as the (300) reflection measured at the La L<sub>II</sub>-edge. In addition to this, the
temperature dependence of  $|\gamma|^{-1}$ , where  $\gamma = 2(a-b)/(a+b)$  is the orthorhombic strain in
the ab-plane, and the macroscopic magnetization is given in Fig. 4(b).

Upon cooling a cooperative Jahn-Teller distorted and antiferro-orbital ordered phase develops at  $T_{\rm JT}$ , which is schematically shown in Fig. 4 (c) [23]. The corresponding structural

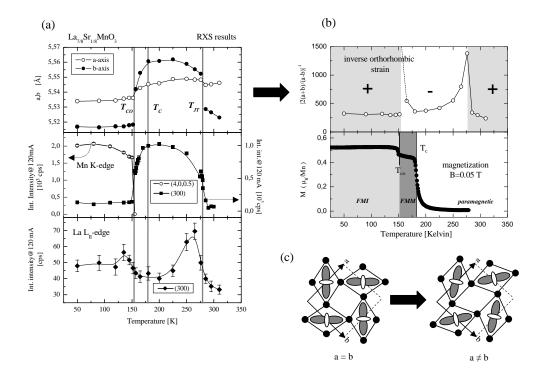

FIG. 4: (a) Comparison of the temperature dependences of the lattice parameters (top), the integrated intensity of the (4,0,0.5) as well as the (300) reflection at the Mn K-edge (middle), and the integrated intensity of the (300) reflection at the La L<sub>II</sub>-edge (bottom). The measurements have been performed with increasing temperature. (b) Temperature dependence of  $|\gamma|^{-1}$ , where  $\gamma = 2(a-b)/(a+b)$  is the orthorhombic strain in the ab-plane (top), and the macroscopic magnetization (bottom). The +/- signs in the top panel indicate the sign of  $\gamma$ . (c) Illustration of the connection between the a, b-splitting, the octahedral distortions, and the octahedral tilts in the cooperative Jahn-Teller distorted phase. Without tilts there is no a, b-splitting, while a finite tilt around the c-axis (perpendicular to the paper plane) results in  $a \neq b$ . The gray and white lobes represent the occupied  $e_g$ -states.

phase transition is clearly reflected by the anomalies of the lattice parameters a and b, which cross at this temperature. At the Mn K-edge, RXS is sensitive to octahedral distortions [16, 24] and, therefore, the strong increase of the (300) reflection at the Mn K-edge signals the onset of cooperative octahedral distortions at  $T_{\rm JT}$ , which are connected to an antiferrorbital ordering. In contrast to the sensitivity to distortions at the Mn K-edge, the (300) reflection becomes sensitive to changes of the cooperative octahedral tilts for photon energies at the La  $L_{\rm II}$ -edge. This means that the increase of the (300) reflection at the La  $L_{\rm II}$ -edge

upon cooling reveals changes in the octahedral tilt structure at  $T_{\rm JT}$ .

With further decreasing temperature, the ab-splitting and the cooperative Jahn-Teller distortions grow as can be seen in the two upper panels of Fig. 4(a), until both reach a maximum at the ferromagnetic ordering temperature  $T_C$ . At the same time, the concomitant reduction of the (300) intensity at the La  $L_{II}$ -edge indicates a coupling between the octahedral tilts and distortions.

The magnetization increase at  $T_C \simeq 180 \,\mathrm{K}$  shown in Fig. 4 (b), marks the onset of ferromagnetic spin order. In agreement with the double exchange (DE) mechanism, the onset of ferromagnetic order below  $T_C$  is connected to an enhanced charge carrier mobility, i.e. metal-like behavior [6]. Therefore, this phase will be referred to as ferromagnetic metallic phase (FMM) in the following. As can be observed in Fig. 4 (a), the *ab*-splitting as well as the intensity of the (300) reflection at the Mn K-edge is reduced drastically with increasing ferromagnetic order. The temperature dependence of the (300) at the Mn K-edge implies a suppression of the cooperative Jahn-Teller distortions in the FMM phase upon cooling. However unlike the behavior observed around  $T_{\rm JT}$ , the suppression of the octahedral distortions is not accompanied by pronounced changes of the (300) intensity at the La  $L_{\rm II}$ -edge below  $T_{\rm C}$ , indicating that the tilt structure hardly changes in the FMM phase.

Finally, the a- and b-axes cross again, the (300) reflection at the Mn K-edge collapses and new superstructure reflections like the (4,0,0.5) reflection shown in Fig. 4 (a) (middle) occur at  $T_{CO}$  upon cooling. In a recent publication we showed that the metal-insulator transition at  $T_{CO}$  is connected to a reordering in the orbital sector, leading to the occurrence of new superlattice reflections [24]. More specifically, we revealed that upon cooling the antiferro-orbital order vanishes at  $T_{CO}$  and an orbital polaron lattice is formed [15]. This orbital polaron lattice leads to enhanced ferromagnetic interactions in agreement with the magnetization jump at  $T_{CO}$  that can be observed in Fig. 4 (b). The moderate increase of the (300) reflection at the La  $L_{II}$ -edge shows that the orbital reordering at the metal-insulator transition is also connected to changes in the octahedral tilt structure.

At last, we note another interesting experimental observation, which concerns the continuous behavior of the (300) reflection at the La  $L_{\rm II}$ -edge across the first order phase transitions at  $T_{\rm JT}$  and  $T_{\rm CO}$ . For the transition into the cooperative Jahn-Teller distorted phase a similar observation has been reported for LaMnO<sub>3</sub> [4]. Moreover, a continuous behavior of the octahedral tilts across  $T_{\rm JT}$  has also been reported in an neutron diffraction study on LaMnO<sub>3</sub>

[25].

#### E. Discussion

The data shown in Fig. 4 demonstrates the coupling of structural and electronic degrees of freedom in  $\rm La_{7/8}Sr_{1/8}MnO_3$ . In the following the coupling between the octahedral tilts to other degrees of freedom will be discussed in more detail.

First we note, that the *ab*-splitting is determined by two effects in general, namely the octahedral tilts and distortions. However, to leading order the *ab*-splitting can be expressed as

$$a - b = (a - b)_0 + 2^{3/2} \delta d \left( 1 + \mathcal{O}(\alpha_0 \delta \alpha) \right) \left( \sin \eta_o + \delta \eta \right)$$
$$\approx (a - b)_0 + 2^{3/2} \delta d \eta_0$$

 $((a-b)_0$ : ab-splitting just above  $T_{JT}$ ;  $\delta d$ : difference between the short and the long Mn-O bond parallel to the ab-plane;  $\alpha_0$ : tilt angle around a- or b-axis just above  $T_{JT}$ ;  $\delta \alpha$ : temperature dependent variation of  $\alpha_0$ ;  $\eta_0$ : the tilt angle around the c-axis above  $T_{JT}$ ;  $\delta \eta$ : temperature dependent variation of  $\eta_0$ ). Assuming moderate variations of the tilt angles, this means that the temperature dependent changes of (a-b) are mainly given by the distortions of the octahedra. This conclusion is verified by the experimental data shown in the two upper panels of Fig. 4(a), where it can be observed that the ab-splitting is directly related to the octahedral distortions detected by the (300) reflection at the Mn K-edge.

Above  $T_{JT}$ , the octahedra are undistorted on average and the ab-splitting can be attributed to the tilting of the octahedra. However, below  $T_{JT}$  the onset of octahedral distortions ( $\delta d \neq 0$ ) changes the ab-splitting according to the above equation. The increasing  $\delta d$  leads to a sign change of the orthorhombic strain with increasing  $\delta d$  (cf. top panel of Fig. 4 (b)) and causes a small ab-splitting close to  $T_{JT}$ . With further decreasing temperature,  $\delta d$  increases yielding a large negative orthorhombic strain. Finally, below  $T_C$  the octahedral distortions are reduced and eventually vanish at  $T_{CO}$ , where the sign of the orthorhombic strain changes back to positive.

Focussing on the temperature regime above  $T_C$ , it can be observed that the intensity of the (300) reflection at the La  $L_{\rm II}$ -edge as a function of temperature behaves similar to  $|\gamma|^{-1}$ , where  $\gamma$  is the orthorhombic strain in the *ab*-plane defined above. In other words, above  $T_C$ 

an increased ab-splitting is related to a decrease of the (300) intensity at the La L<sub>II</sub>-edge. This shows that the variations of the octahedral tilts above T<sub>C</sub> are directly coupled to changes of the lattice strain; i.e. the elastic energy of the lattice. It can therefore be concluded that in the paramagnetic phase the antiferro-orbital ordering and the tilt structure are coupled mainly via the elastic energy of the lattice.

However, this situation changes below the ferromagnetic transition temperature  $T_C$ . Although the ab-splitting is strongly reduced in the FMM phase below  $T_C$  ( $|\gamma|^{-1}$  diverges), the (300) intensity at the La  $L_{II}$ -edge reveals that there are almost no changes of the octahedral tilt structure. This implies that below  $T_C$ , the tilts are not only influenced by changes of the elastic energies. In fact, in the FM ordered phases the DE mechanism becomes important, which favors larger Mn-O-Mn bond angles, i.e. smaller tilts.

The stabilization of a particular octahedral tilt structure in  $A_{1-x}B_xMnO_3$  is mainly attributed to the coordination of the A/B-sites [26]. More specifically, different tilt structures lead to different coordinations of these sites and, hence, yield different energies. However, the experimental data presented here reveals that the octahedral tilt structure in  $La_{7/8}Sr_{1/8}MnO_3$  is also strongly affected by the electronic properties related to the correlated Mn:3d and O:2p electrons. One coupling mechanism between the correlated electron system and the octahedral tilts is given by the transfer integral t, which depends on the Mn-O-Mn bond angles and, therefore, on the octahedral tilts. Since the physics of doped manganites are governed by various competing interactions, the coupling of the electronic degrees of freedom and the tilt structure observed here, is expected to have a significant impact on the stability of the various ordered phases.

### F. Conclusion

The energy, azimuthal and temperature dependence of the symmetry forbidden (300) reflection at the La  $L_{II}$ -edge has been investigated. At this energy the (300) reflection is sensitive to changes of the octahedral tilt order. A resonance of the (300) reflection at the La  $L_{II}$ -edge has been observed. Furthermore, the resonant scattering involves a rotation of the beam polarization ( $\sigma\pi$ -scattering) and displays a pronounced azimuthal dependence. These characteristic features of the resonant scattering at the La  $L_{II}$ -edge are in full agreement with the model calculation presented in Sec. C and LSDA+U calculations. Therefore, we

conclude that the intensity of the (300) reflection at the La  $L_{II}$ -edge reflects changes of the tilt structure.

The presented experimental results show that the various ordering phenomena observed in  $La_{7/8}Sr_{1/8}MnO_3$  couple to the octahedral tilt structure. This conjecture is further supported by the effects of chemical pressure on  $La_{7/8}Sr_{1/8}MnO_3$ : Upon substituting La by smaller Pr in  $(La_{1-y}Pr_y)_{7/8}Sr_{1/8}MnO_3$ , the mean radius of the corresponding lattice site (the so-called A-site) can be reduced in a systematic way, resulting in an increase of the octahedral tilts [26]. Upon increasing the Pr-concentration y the transition temperature  $T_{CO}$  is considerably reduced, while  $T_{JT}$  strongly increases, manifesting the impact of the octahedral tilting on the ordering phenomena in  $La_{7/8}Sr_{1/8}MnO_3$  [14]. These results are corroborated by the observed dependences of  $T_{JT}$  and  $T_{CO}$  on applied external pressures [27, 28].

At other doping levels there are as well clear indications for the relevance of octahedral tilts for the physical properties of doped manganites. For instance, the mean ionic radii of the A-site have also a strong influence on the stability of the charge and orbital ordered CE-phase in half doped manganites [29]. This points to the important role of the octahedral tilt structure for the physics of doped manganites in general.

The tilt order is not only of importance in the case of manganites, as already mentioned in the introduction. This order parameter also plays a crucial role for the physics of other transition metal oxides like nickelates and cuprates. Also in these cases the RXS technique is perfectly suited to study octahedral tilt order and its coupling to other degrees of freedom.

#### Acknowledgments

We would like to thank M. v. Zimmermann for the careful reading of our manuscript and many useful discussions. We are very grateful to H. Dosch for his support. This work was supported by the Deutsche Forschungsgemeinschaft.
